**Objectives:** To investigate the ability of listeners to detect, identify, locate, and characterize individual sound sources in noise, especially when the sound source is a time-delayed and filtered reflection from the ceiling and the floor (e.g., Begman 1990; Koehnke & Beig 1996). In such an environment, listeners, especially older adults, often find it difficult to process acoustic signals (e.g., speech), even though they can functionally identify a sound (e.g., Cheeman et al. 1995; D'Amico et al. 1984; D'Amico 1983; Gelfand et al. 1988; Gordon-Salant & Fitzgibbon 1995; Helfe & Wilber 1990; Nabelek & Robinson 1982; Nabelek 1988; Pichon-Fleury et al. 1995; Slat & Phillip 1996). Hearing-impaired hearing-aged decrease in some of the perceptual processes that support a dichotic analysis might be contributing to the difficulty that older adults experience in noise, especially in an environment.

**Design:** In Experiment 1, listeners were asked to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL). In Experiment 2, listeners were asked to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL).

**Results:** The results of Experiment 1 show that listeners were able to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL). The results of Experiment 2 show that listeners were able to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL).

**Conclusions:** The results of this study suggest that listeners are able to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL). The results of this study suggest that listeners are able to detect, identify, and locate a target sound source (BIC) in a background of noise (10 dB SPL) and a target sound source (BIC) in a background of noise (10 dB SPL).

Abstract: This study investigated the ability of listeners to detect, identify, locate, and characterize individual sound sources in noise, especially when the sound source is a time-delayed and filtered reflection from the ceiling and the floor (e.g., Begman 1990; Koehnke & Beig 1996). In such an environment, listeners, especially older adults, often find it difficult to process acoustic signals (e.g., speech), even though they can functionally identify a sound (e.g., Cheeman et al. 1995; D'Amico et al. 1984; D'Amico 1983; Gelfand et al. 1988; Gordon-Salant & Fitzgibbon 1995; Helfe & Wilber 1990; Nabelek & Robinson 1982; Nabelek 1988; Pichon-Fleury et al. 1995; Slat & Phillip 1996). Hearing-impaired hearing-aged decrease in some of the perceptual processes that support a dichotic analysis might be contributing to the difficulty that older adults experience in noise, especially in an environment.

(Ear & Hearing 2009;30:273-286)

## INTRODUCTION

Perhaps the most intriguing question in a dichotic analysis is how listeners are able to detect, identify, locate, and characterize individual sound sources in noise, especially when the sound source is a time-delayed and filtered reflection from the ceiling and the floor (e.g., Begman 1990; Koehnke & Beig 1996). In such an environment, listeners, especially older adults, often find it difficult to process acoustic signals (e.g., speech), even though they can functionally identify a sound (e.g., Cheeman et al. 1995; D'Amico et al. 1984; D'Amico 1983; Gelfand et al. 1988; Gordon-Salant & Fitzgibbon 1995; Helfe & Wilber 1990; Nabelek & Robinson 1982; Nabelek 1988; Pichon-Fleury et al. 1995; Slat & Phillip 1996). Hearing-impaired hearing-aged decrease in some of the perceptual processes that support a dichotic analysis might be contributing to the difficulty that older adults experience in noise, especially in an environment.

## Adult Speech Analysis

To perceptually separate a target from the background in a dichotic analysis, the auditory system of the listener has to be able to differentiate the target from the background and to time-delay and filter the reflection from the ceiling and the floor (which will not be a high-frequency component of the signal coming from the target). In the end, to efficiently process the signal coming from an attended sound source in a noisy environment, the auditory system needs to conduct two major perceptual operations: (1) integrate the target from the background and (2) segregate the target from the background. If there is a deficit in the first operation, the sound reflection themselves, rather than being perceptually integrated into the overall scene, could split off (Blaettl & Lindemann 1986) from the target and be perceived as separate auditory events. If there is a deficit in the second operation, information from the overall scene might be partially integrated with that of the target, leading to confusion. The effect, to be capable of determining the location of a sound source, is a function of different time and frequency dimensions as well as the same

**I n t r o d u c t i o n**

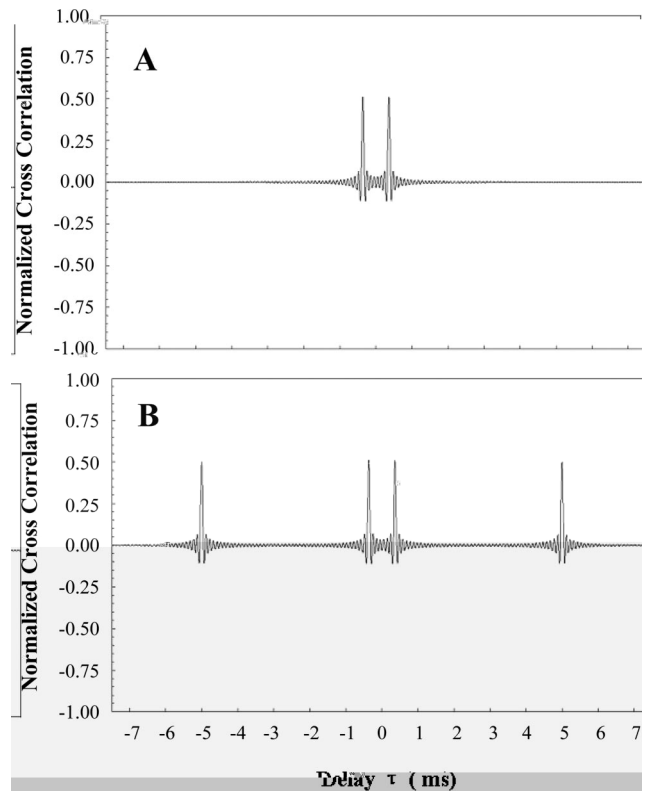

When the delay between the direct wave from the source and one of its reflections is sufficiently short (e.g., 5–10 ms or less, depending on the time scale), all non-partially absorbed reflections are perceived by the direct wavefront (e.g., Li et al. 2005), leading to a fused sound image whose point of origin is perceived to be at or near the location of the sound source. This phenomenon is called the precedence effect because the direct wavefront takes precedence over the correlated wavefront (Blauert 1997; Li & Yue 2002; Litovsky et al. 1999; Wallach et al. 1949). The strength of this integration is a precedence effect in a large degree determined by the delay between the direct and reflected waves. When this delay is sufficiently short (less than the echo threshold), the direct wave and the reflection are fused into a single image, in which the perceived location is at or near the location of the source. The partial extent of the fused image will exceed that observed in the anechoic environment, an effect referred to as the precedence effect (Li et al. 2005).

time interval, one at each ear. When the interaural correlation is 0.25, 0.50, or 0.75, listeners perceived one difference in the median plane, and two additional ones laterally. In addition, the compactness, number, and placement of images depend on the degree of interaural correlation. It is not clear, however, whether the age-related change in the ability to detect or process interaural correlation. Nevertheless, we would predict that an age-related diminution in the ability to detect and process interaural correlation, especially when one of the sound sources is delayed with respect to the other, could lead to a more fragmented auditory scene in older adults, which would increase the difficulty of attending to and processing information from the target talker.

**Unilateral Cross-correlation and Delayed Sound Field**

Detecting a correlation between two signals in the sound field is somewhat more complicated than detecting a correlation under headphone conditions. Assume for the moment that the two sound sources are located 45 degrees to the left and right of the listener in an anechoic environment, playing independent band-limited white noise ( $g(t)$  on the left loudspeaker and  $h(t)$  on the right loudspeaker), both having bandwidth  $W = 10$  kHz. To simplify the calculation, we can measure, in the absence of the listener, the correlation at the position that would be occupied by the listener's left and right ears. This is equivalent to assuming that the head does not scatter sound and that only the delay between the sound arriving at the near and far ears needs to be considered (at 45 degrees, the delay,  $\delta$ , is approximately 0.363 m). In this case, the signal arriving at the position occupied by the left ear is  $g(t) + h(t - 0.000363)$ , while the signal arriving at the position occupied by the right ear is  $g(t - 0.000363) + h(t)$ . The normalized cross-correlation function for this case is shown in Figure 1 (top panel). Note that the normalized cross-correlation function has two peaks at  $\tau = -0.363$  m and  $\tau = 0.363$  m. The two peaks represent the cross-correlation between the direct sound arriving at the near ear from an off-midline source and the same sound arriving at the far ear. Note that the two peaks will always be present when the two sound sources are symmetrically displaced from the midline.

When the two noise sources are correlated and the left-loudspeaker noise leads the right-loudspeaker noise by  $\gamma$  seconds, the signal arriving at the left ear is  $g(t) + g(t - \delta - \gamma)$ , while the signal arriving at the right ear is  $g(t - \delta) + g(t - \gamma)$ , when measurements are taken in the absence of the head. Figure 1 (bottom panel) also plots the normalized cross-correlation function\* for  $\gamma = 5$  ms and  $\delta = 0.363$  m. Note that this cross-correlation function has two peaks on each side of  $\tau = 0$ , one corresponding to the interaural delay (0.363 m) and one corresponding to the delay between the correlated sound playing on the left- and right-loudspeakers (5 ms). A loudspeaker delay decreases the peak in the cross-correlation function caused by the delay shift accordingly (and becomes one when  $\tau = 0$ ), while the two peaks caused by  $\delta$  are unaffected by an delay between the loudspeakers. Hence, the listener could discriminate between correlated and independent

noise based on their ability to detect a peak in the cross-correlation function at a delay, although between the correlated sound coming from the two loudspeakers.

In Figure 1, it is assumed that the ears are not attenuated because of the shadow cast by the head. Figure 2 shows that when the head-related transfer functions are included in the computation of the normalized cross-correlation function, the interaural delay,  $\delta$ , an enhancement of the peak at  $\tau = \gamma$  m, and a substantial diminution of the peak at  $\tau = -\gamma$  m. However, the decrease in the peak caused by the interaural delay is the same for both independent and correlated noise when the sound is not shadowed. As a result, the peak contains no information as to whether or not the sound is correlated. Hence, the only way to determine whether or not the sound is correlated from the cross-correlation function is to be able to identify the peak at  $\tau = 5$  ms.

The calculation will be further complicated if the loudspeakers are enclosed in a reverberant environment (e.g., a sound-treated chamber, as they are in the hearing experiment), which will introduce the peak caused by sound reflection. However, a number of studies have indicated (e.g., Feman et al. 1999; Kidd et al. 2005; Koehnke & Beisinger 1996; Zek et al.

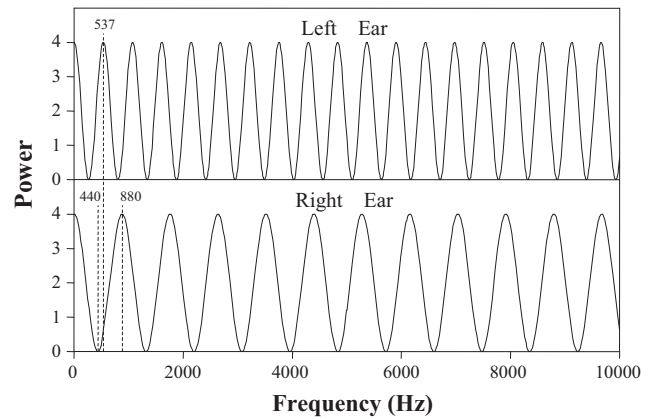

Figure 3 plots the long-term power spectra at the position occupied by the left (top panel) and right (bottom panel) ears for a band-limited noise,  $g(t)$ , (10 kHz,  $N_0 = 1$ ) played over a loudspeaker located 45 degrees to the left of the listener and an identical earphone delayed by  $\gamma = 1.5$  m located 45 degrees to the right of the listener so that the interaural delay is again equal to 0.363 m. If we ignore the sound head shadow effect, the signal arriving at the left ear is  $g(t) + g(t - 0.0015 - 0.000363)$  and the signal arriving at the right ear is  $g(t - 0.000363) + g(t - 0.0015)$ . Hence, the power spectrum at the left ear is  $2 + 2 \cos(2\pi f \times 0.001863)$ , and the power spectrum at the right ear is  $2 + 2 \cos(2\pi f \times 0.001137)$ . Because of contrast, if the two noises are independent (again assuming no head shadow effect), the power spectrum has a minimum value of 2 across the entire spectrum. If the audio system were to compare the output of a right ear monaural filter centered at 440 Hz to one centered at 880 Hz, the difference between the output of the two filters would be large when the noise frequencies are correlated and 0 when the noise frequencies are independent. Alternatively, if the audio system were to compare the left- and right-ear monaural filter centered at 537 Hz, the interaural difference in the output of the two filters would be large when the left- and right-loudspeaker noise frequencies are correlated and negligible when the noise frequencies are independent.

2004), the effect of adding the reflection is to increase the perceptual difficulty encoded by human observers and a more likely topology is an additional cue that would aid them in discriminating between correlated and independent sound. Finally, it should be noted that the cross-correlation function shown in Figure 1 and 2 assumes that the time delay is infinite in duration. Cross-correlation function computed over a finite and more realistic time period would be, in general, broader than the depicted here.

**Upper Section: Interaural Phase and Sound Field**

In the sound field, the degree of correlation between the left and right noise signals is determined by the interference pattern that the ears receive when the two signals are added. If a band-limited noise is added to itself after a delay of  $\gamma$  sec, the long-term power spectrum of the sum is no longer flat but rippled (comb filtering, Nadin et al. 1979). If the spectrum level of the original noise is  $N_0$ , the spectrum level of the summed noise will be  $N_0(2 + 2 \cos[2\pi f \gamma])$ . However, if the two noises are independent, the long-term spectrum level is  $2N_0$  for all frequencies within the bandwidth of the noise. Hence, when left and right correlated signals are added, a ripple pattern will be observed in the spectrum, with the effect of modulation being determined by the delay.

Hence, the audio system could make use of both monaural and binaural spectral cues, as well as a cross-ear correlation to determine whether the sound is a reflection from one direction or a delayed reflection of another reflection that had a different period. Age-related changes in the ability to detect interaural spectral difference, a semantic ripple in the monaural spectrum, or age-related changes in the ability to detect an interaural correlation (especially when the ears are

This depiction assumes that the head shadow is not considered. If the sound had been taken into consideration, the difference between peak and trough and the average power change with frequency because of the HRTF. Hence, Figure 3 depicts an upper limit to the functional availability of the monaural and binaural spectral cues.

delay), could affect the ability of older adults to perceive the dichotic scene as effectively as younger adults.

**Task**

In experiment 1 of the present study, we assessed the age-related difference in the ability to detect a BIC when broadband noise is presented either over headphones or over loudspeakers. Note that when the BIC is presented over headphones, only binaural cues are available. However, when the same signal is presented in the sound field, the listener could use comb-filtering effects to supplement the information obtained through interaural correlation. Hence, if listeners could use comb-filtering effects to detect a BIC, we would expect to find better performance in the sound field than under headphones presentation.

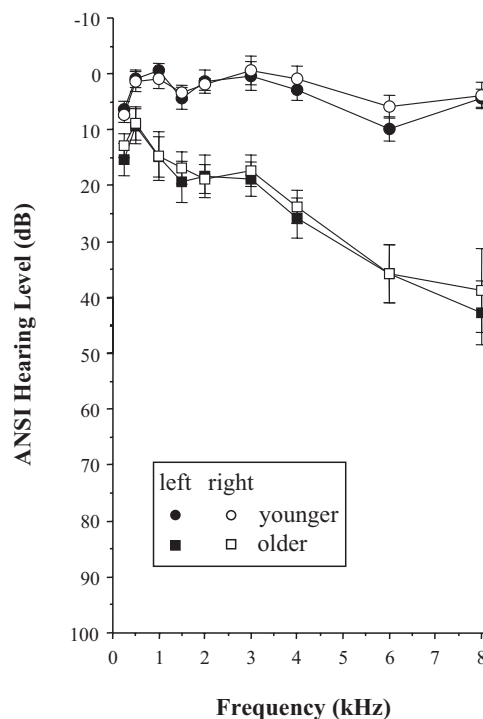

Based on the results of experiment 1, in experiment 2 we examined the longest interaural delay at which a BIC with a long duration (100 ms, which is well above the BIC duration threshold for the interaural delay) is detectable, in both younger adults and older adults. We also examined the longest interaural delay that could be detected to evaluate the degree to which monaural and binaural cues could aid in the detection of a BIC.

**MATERIALS AND METHODS**

**Experiment 1: BIC Detection Thresholds and Age-Related Differences**

**Participants** • Ten younger adults (6 female, 4 male, 19–21 years old, recruited from the University of Toronto at Mississauga) and 10 older adults (3 female, 7 male, 64–75 years old, recruited from the local community) participated in experiment 1. None of the participants had a history of hearing disability, and none used hearing aids. All participants gave their informed consent to participate in the experiment and were paid a modest stipend for their participation. The participants did not participate in experiment 2.

The younger adults and 6 of the 10 older adults had pure-tone air-conduction thresholds less than 25 dB HL between 0.25 and 3 kHz. Four older adults had hearing levels at least at one of the test frequencies that were greater than 25 dB HL but less than 35 dB HL. Hearing thresholds for all participants were monaural (interaural difference less than 15 dB at each frequency). Figure 4 presents average hearing levels for both age groups as a function of frequency. The threshold for all of the younger adults were well within the normal range. On average, the older adults' thresholds were 8 to 10 dB poorer than those of younger adults for frequencies less than 2 kHz. For frequencies higher than 2 kHz, the threshold difference increased and differed by as much as 40 dB at the highest frequency tested. Although older adults with hearing in this range are usually referred to as having clinically normal hearing, the average characteristics are being in the early stage of presbycusis. Hence, the age-related performance differences are likely reflecting a clinical decline in a number of auditory functions, including the ability to detect temporal processing (e.g., Gordon-Salant & Fitzgibbon 1995, 1999; Schneider et al. 2002).

**Sound calibration** • During the session, the participant was seated in a chair at the center of an Industrial Acoustic Company sound-attenuated chamber, whose internal dimensions were 283 cm in length, 274 cm in width, and 197 cm in height. The ear level distance, which measured the time of the first 10 dB of the decay and was related to subjective judgment of ear distance (Badler 1991), were 0.093, 0.135, 0.090, 0.079, 0.088, and 0.086 seconds for frequencies of 125, 250, 500, 1000, 2000, and 4000 Hz, respectively.

**Sound field generation and delivery** • Gaussian broadband noise (bandwidth = 0–10 kHz; sampling rate = 20 kHz), in which duration was 1000 ms, was digitally synthesized by generating 20,000 independent random normal deviates. Hence, the average spectrum of the digital noise was flat over the region from 0 to 10 kHz. This 1-millisecond, linear-on- and off- amplitude was applied to each noise burst. The digital signal was converted to analog form using Tucker-Daichi Technologies (TDT) DD1 digital-to-analog converter under the control of a Dell computer with a Pentium II processor. The analog output was low-passed at 10 kHz with TDT FT5 filter, attenuated to a programmable attenuator (TDT PA4, for the left and right channel), and fed into a headphone buffer (TDT HB5). The output from the headphone buffer was either terminated by a pair of balanced headphones (Telephonic TDH-49P) or amplified via a Hamman/Kardon portable amplifier (HK3370) and then delivered from two balanced loudspeakers (Electro-Medical Instrument, 40 cm). The two loudspeakers were in the frontal azimuthal plane at the left and right 45° position monaurally with respect to the median plane, respectively. The distance between each of the two loudspeakers to the center of the participant's

be (193 cm in length, 183 cm in width, and 198.5 cm in height), (2) the analog output from the headphone buffer is amplified via a different power amplifier (Technic, SA-DX950), and (3) the distance from each of the two loudspeakers to the center of the participant's head is 1.03 m. For the chamber used in experiment 2, the ear level decay times were 0.089, 0.035, 0.023, 0.044, 0.059, and 0.025 seconds for frequencies of 125, 250, 500, 1000, 2000, and 4000 Hz, respectively.

**Procedure** • Two 1000 ms intervals of correlated Gaussian broadband noise were presented either over headphones or loudspeakers. The right-headphone (loudspeaker) noise in one of the intervals was a copy of the left-headphone (loudspeaker) noise. The right-headphone (loudspeaker) noise in the other interval was a copy identical to the left-headphone (loudspeaker) noise except for the substitution of a long (100 ms) BIC introduced into the middle of the 1000 ms noise burst. In substituting an independent noise segment in the left channel, in each trial, the BIC had equal probability to be randomly assigned to one of the two intervals of a 2IFC paradigm. The two intervals on a trial were separated by 1000 ms. For each interval, the 1000 ms noise coming from the left headphone (or the left loudspeaker) was followed by the 1000 ms noise coming from the right headphone (or the right loudspeaker) with the length of the interval randomly manipulated (see below). That is, the interval delay was applied to the whole interval both on an ongoing portion. Because the independent 100 ms noise segment was associated with the BIC, a copy was introduced in the center of the noise before the imposition of the signal delay, the uncorrelated segment itself was delayed in the right channel to the left by the same amount as the whole interval delay. For each noise segment generated for each trial, the participant was asked to identify which of the two intervals contained the BIC.

The participant initiated a trial by pressing a button on the response box. The starting interval delay in a testing session was 1 ms. The interval delay was increased after three consecutive correct identification of the interval containing the BIC and decreased after one incorrect identification, using a three-up-one-down procedure (Levitin, 1971). The initial step size of changing the interval delay was 8 ms, and the step size was halved by a factor of 0.5 in each interval of duration until the minimum size of 1 ms was reached. Feedback was provided at each trial. A testing session terminated after 12 intervals in duration, and the threshold for that session was defined as the average delay for the last eight intervals. Testing sessions were repeated four times for each participant, and the best threshold was then averaged to obtain an estimate of the limit of each participant's ability to detect a waveform information available in the noise.

**RESULTS**

**Experiment 1: BIC Detection Thresholds and Z-Scores for Loudspeakers and Headphones**

Figure 7 shows the group average of the best BIC detection threshold at which the BIC could be detected under both the headphone-timelation condition and the loudspeaker-timelation condition for the two age groups. Under either the

headphone-timelation condition, younger participants were able to detect shorter BIC than older participants, indicating a reduction in sensitivity to the BIC with age. Under the headphone-timelation condition, on average, younger participants could detect a BIC approximately 4.5 ms long (median = 4 ms), whereas older participants could detect a BIC whose duration was approximately 8.5 ms (median = 8.1 ms). Under the loudspeaker-timelation condition, the thresholds for detecting the BIC were 2.3 ms (median = 2.4 ms) for the younger group and 3.4 ms (median = 3.2 ms) for the older group. The best BIC detection for individual participants under the timelation condition are shown in Figure 8, Table 1 (for younger participants) and Table 2 (for older participants). Note that the performance variability in the threshold for older than for younger adults, which is of the order of having a detection threshold within the range of those observed for younger adults. This increase in variability with age has been found in

**TABLE 1. BIC** 10 ( )

BIC, break in correlation.

the threshold. For example, Schneider and Pichon-Affelle (2001) showed that the ear man older adult had gap detection threshold that were within the range found for younger adult, a substantial number had the threshold in the center of this range.

At the between-subject (age, older) but not within-subject (headphone, loudspeaker) mixed analysis of variance (ANOVA) did not reveal a significant interaction between age group (age, older) and timbral presentation type (headphone, loudspeaker) ( $F_{1,18} = 2.890$ ;  $MSE = 7.338$ ;  $p = 0.106$ ) but did reveal that the main effect of timbral presentation type ( $F_{1,18} = 18.385$ ;  $MSE = 7.338$ ;  $p < 0.001$ ) and age group ( $F_{1,18} = 7.087$ ;  $MSE = 9.160$ ;  $p = 0.016$ ) were both significant. Hence, older adult have higher threshold than younger adult, and the efficiency evidence to reject the hypothesis that, in the sound field, combining center of the threshold by the same amount in both younger and older adult when the interdelay between left and right noise.

An examination of Table 2 indicates the presence of a potential outlier in the headphone condition (participant AM). To check for the outlier a separate ANOVA with this participant removed. The main effect of age and condition remained significant, and the interaction between age and condition. Hence, we have retained this outlier in the remaining analyses.

For younger participant, the correlation between the threshold and loudspeaker presentation and threshold and headphone presentation was 0.521, which was not significant ( $F_{1,8} = 2.987$ ;  $MSE = 0.734$ ;  $p = 0.122$ ). For older participant, the correlation between the threshold and loudspeaker presentation and threshold and headphone presentation was 0.104, which was also not significant ( $F_{1,8} = 0.088$ ;  $MSE = 3.056$ ;  $p = 0.774$ ).

To evaluate the BIC threshold related to a diometric threshold, we correlated BIC threshold with pure tone age (PTA, averaged across the two ears) for both low-frequency (0.25-2 kHz, LF-PTA), and high-frequency (3-8 kHz, HF-PTA) in both younger and older adult. None of the correlations were significant in either younger or older adult. For the younger adult, the correlation between BIC threshold and LF-PTA was  $-0.1$  ( $p > 0.05$ ) and  $0.156$  ( $p > 0.05$ ) for headphone and loudspeaker presentation, respectively; the correlation between BIC threshold and HF-PTA was  $0.541$  ( $p > 0.05$ ) and  $0.262$  ( $p > 0.05$ ) for headphone and loudspeaker presentation, respectively. For older adult, the

correlation between BIC threshold and LF-PTA was  $0.272$  ( $p > 0.05$ ) and  $-0.04$  ( $p > 0.05$ ) for headphone and loudspeaker presentation, respectively; the correlation between BIC threshold and HF-PTA was  $0.284$  ( $p > 0.05$ ) and  $0.434$  ( $p > 0.05$ ) for headphone and loudspeaker presentation, respectively. Hence, there is little evidence that BIC threshold are correlated with the low- or high-frequency PTA in younger or older adult.

**Experiment 2: Main Effects of Age and D**

Figure 9 shows the group mean of the longest inter-onset delay at which younger or older participant were able to detect a 100 ms BIC. Under the headphone-timbral condition, both the mean (13.8 ms) and median (11.9 ms) threshold for younger participant were longer than those (mean = 8.6 ms; median = 8.7 ms) for older participant. Also, under the loudspeaker-timbral condition, both the mean (23.5 ms) and median (26.1 ms) threshold for younger participant were longer than those (mean = 10.6 ms; median = 11.2 ms) for older participant. Thus, there was a substantial reduction in the ability to detect an inter-onset delay in age.

At the between-subject (age, older) but not within-subject (headphone, loudspeaker presentation) ANOVA found that the interaction between age group and timbral presentation type (headphone or loudspeaker) was significant ( $F_{1,16} = 5.722$ ;  $MSE = 23.349$ ;  $p = 0.029$ ), as was the main effect of age group ( $F_{1,16} = 19.959$ ;  $MSE = 36.299$ ;  $p < 0.001$ ), and timbral presentation type ( $F_{1,16} = 13.149$ ;  $MSE = 23.349$ ;  $p = 0.002$ ). Separate ANOVA for headphone and loudspeaker presentation showed that the age effect was significant for both loudspeaker ( $F_{1,16} = 20.805$ ;  $MSE = 35.579$ ;  $p < 0.001$ ) and headphone-timbral condition ( $F_{1,16} = 4.899$ ;  $MSE = 24.070$ ;  $p = 0.042$ ). Hence, the interaction effect indicates that the increment in performance going from headphone to loudspeaker condition is a large for younger than for older adult.

To further explore the nature of the interaction, we plotted the longest delay between left and right noise at which each individual could detect a 100 ms BIC in the sound field as a function of the longest delay threshold could detect a 100 ms BIC under headphone condition (Fig. 10). The dotted line (slope = 1.0) represents the equal delay predicted if there were no difference between headphone and sound field condition. This figure shows that all participant but one performed better under sound-field condition than under headphone condition. Participant, five of the younger adult performed markedly

**TABLE 2. BIC** 10 ( )

Participants	BR	AG	ES	BM	JZ	LW	GH	JSF	EW	AM
Loudspeaker	2.8	3.9	4.0	6.1	5.7	3.7	1.0	2.7	1.4	2.4

bate under on-field condition than under headphone condition (the e e data point are farther from the diagonal line). The e e l get that some on ge participant (but no olde one) seem to de i e a btantial benefit under on field condition (more than doubling the longest delay at which the could detect a BIC), e enthogh the e e not nece ail the bet participant under e i he on-field condition o headphone condition. Hence, the ge e impo ement in the pe fo mance of on ge ad l when going from headphone to loud peak e pe entation can be attributed to the fact that half of the on ge ad l impo ed maked l, he ea the o he half ho ed little impo ement. The longest delay for individual participant under each of the ot pe of tim lation condition are al o ho n in Table 3 (for on ge participant) and Table 4 (for olde participant). Unlike the

ca e fo d a ion the hold, he e the e i mo e a iabili among the on ghtan among the olde litene. F the mo e, the e i no indication that olde ad l benefit from the loud peak e pe entation, he ea half of the on ge ad l e hibi a la ge benefit from the loud peak e pe entation.

Fo on ge participant, the co elation between the the hold under headphone-tim lation condition and the under loud peak e-tim lation condition a 0.214, which a not ignificant ( $F_{1,8} = 0.383$ ;  $MSE = 65.362$ ;  $p = 0.553$ ). For olde participant, the co elation between the the hold under headphone-tim lation condition and the under loud peak e-tim lation condition a 0.422, which a al o not ignificant ( $F_{1,6} = 1.299$ ;  $MSE = 2.919$ ;  $p = 0.298$ ).

To ee h e the ma im m i te on d delay e e elated to a diom ic the hold, e co elated the i te on d delay with PTA for both lo (0.25 2 kHz, LF-PTA), and high (3 8 kHz, HF-PTA) frequency. For the on ge ad l, the co elation between the longest delay at which a BIC could be detected and LF-PTA e e 0.288 ( $p > 0.05$ ) and 0.291 ( $p > 0.05$ ) for headphone and loud peak e pe entation, e p e i el; the co elation between the longest delay and HF-PTA e e 0.399 ( $p > 0.05$ ) and 0.276 ( $p > 0.05$ ) for headphone and loud peak e pe entation, e p e i el. For olde ad l, the co elation between the longest delay and LF-PTA e e 0.282 ( $p > 0.05$ ) and  $-0.15$  ( $p > 0.05$ ) for headphone and loud peak e pe entation, e p e i el; the co elation between the longest delay and HF-PTA e e 0.338 ( $p > 0.05$ ) and  $-0.27$  ( $p > 0.05$ ) for headphone and loud peak e pe entation, e p e i el. Hence, the e i e little e idence that the longest i te on d delay at which a 100 m BIC can be detected is co elated with the lo -o high-frequency PTA in on ge o olde ad l.

## DISCUSSION

total energy, we calculated the BIC threshold in a diometric threshold equal for noise and older adult at both high and low frequencies. The correlation, however, provided little evidence for a relationship between a diometric hearing loss and energy to BIC. Hence, it seems more likely that loss in energy to BIC is related to the age-related change in the auditory stem, which also influences neural synchrony. Perioctidies have shown that older listeners with normal hearing have malle making level difference (MLD) than noise-adapted listeners (e.g., Goebel et al. 1994; Olsen et al. 1976; Pichon-Flelle & Schneide 1991, 1992, 1998; Soe et al. 1998). Pichon-Flelle and Schneide (1992) have suggested that malle MLD in older adults is caused by loss in temporal synchrony between the onset (i.e., an increase in temporal jitter; D. lach 1972). Hence, age-related loss in temporal synchrony could account for both malle MLD and higher BIC threshold in older than younger adults.

Perioctidies of functional magnetic resonance imaging and magnetoencephalography studies have suggested that in humans the auditory cortex is involved in processing interaural correlation (e.g., B. dd et al. 2003; Chai et al. 2005; Hall et al. 2005; Zimme & Macal 2005). Thus, it is important in future studies to explore whether the age-related alteration of the central representation of the change in interaural correlation at the cortical level.

Another possibility is that age-related change in the ability to detect a BIC could reflect age-related change in the level of the temporal index of the interaural comparison. Several investigations have reported that binaural comparison is performed within a temporal window applied to the input to the onset (e.g., Benstein et al. 2001; Mooe et al. 1988). According to this notion, the auditory stem effect in integrated binaural information falling within this temporal window. Hence, when there is a change in an interaural correlation during this window, this integration process of the internal effect is a result of this change. For example, if observed to center the temporal index at the midpoint of each of the broadband noise presented on a 2IFC trial in experiment 1 (with the BIC occurring randomly in the center of one of the noise), the correlation comparison interaural information available in this window for each of the noise to determine which one contained the BIC. Assuming that noise and older adults received the same amount of information to reach the threshold for detecting a BIC (e.g., the same difference in interaural correlation), age difference in the hearing loss of the temporal index could lead to age difference in performance. For example, suppose the partici-

part in experiment 1 applied a constant temporal index (a constant index index used here to simplify the description of how age difference in temporal index could account for age difference in detecting a BIC) to the time-averaging interaural correlation. For the diotic noise with the BIC, the interaural correlation would be 1.0 for both age groups, independent of temporal index (assuming that the temporal index is smaller than the length of the stimulus). However, the interaural correlation for a noise with a hot BIC will depend on temporal index. Suppose the constant index is for noise and older adults are 4 and 8 ms, respectively. When a 6 ms BIC is presented, the interaural correlation of the index signal would be 0 for noise and 0.5 for older than for older adults because older adults would be computing interaural correlation over 8 ms of left- and right-ear signals. If the correlation is 1.0 for the first and last 6 ms of the 8 ms comparison and averaging the middle 6 ms. Hence the difference in interaural correlation between the noise segments with and without a BIC would be larger for noise than for older adults, leading to an age-difference in the ability to detect a BIC.

When the stimulus is presented over loud peaks, the sound field provided certain additional cues, such as the induced binaural combination effect (Nain et al. 1979). These cues could aid listeners to detect the transient peak in interaural correlation. The data from experiment 1 suggest that both noise and older adults are able to detect the cue to detect a hot BIC when the cue is presented (loud peaks presentation) than the cold when the cue is absent (headphone presentation). Moreover, even though older adults seemed to benefit more than noise and older adults from a switch from headphone to the sound field (Fig. 7, the threshold decrease in older adults = 5.1 m; the threshold decrease in noise and older adults = 2.2 m), the interaction of age group and stimulus presentation type for the duration threshold was not statistically significant. Hence, when there is no delay between the left- and right-ear onset, we cannot reject the hypothesis that noise and older adults benefit equally from the addition of sound-field cues.

THE EFFECTS OF PRESENTATION MODE AND INTERAURAL CORRELATION ON BIC DETECTION

The present study investigated how long a form of information is available to the listener by measuring the range of interaural delay in which a long-duration (100 ms) BIC is available under headphone presentation (according to the

TABLE 4. T

<sup>3</sup>In the Benstein et al. (2001) model, the meaning effect that the index on binaural comparison is indexed by computing S, the average of the temporal index of the probe portion of the stimulus (e.g., a BIC), and dividing it by the total average of the temporal index of the entire stimulus. The internal effect is a result of an interaural comparison then assumed to be given by multiplying the internal effect by S.

... of the experiment 1, at the zero interaural delay, the 100 ms duration is well above the BIC threshold for all the younger and older participants). Two of the younger participants were able to detect the occurrence of the 100 ms BIC when the delay between the two ears was up to 25 ms in the headphone condition (Fig. 10). Note that the delay threshold is variable for younger adults, indicating a wide range of individual differences. Older adults, however, are much more uniform in their performance to detect BIC at long delays. Recall, however, that long delays are held constant to better performance. Hence age-related performance decrement would manifest themselves as a lower threshold. Because the threshold is bounded at the lower end by the value of 0, poor performance in a group of older adults would tend to reduce the variance in this group, as is observed in Figure 10. Hence the pattern of results in experiment 2 suggest that as people age, their capacity to detect a change in correlation diminishes.

They seem to be too poor a predictor in which the addition of some ongoing adult could bridge temporal delay greater than 15 ms between correlated left and right ears. First, the cross-correlation function relating the output of matched narrowband, left- and right-ear a d i o file could have a substantial peak within the range of delay that is physiologically realistic (-1.5 to 1.5 ms). If that were to occur, it would permit the addition of a delay between correlated and independent noise, because the cross-correlation function for two independent noises would be zero for all delays.

To see how this could occur, let  $y(t)$  be the output of a narrowband, left-ear a d i o file to a broadband noise,  $g(t)$ . If the file is linear and high-pass independent, then the output of the matching right-ear file to  $g(t - \gamma)$  is  $y(t - \gamma)$ . Therefore, we can compute a cross-correlation function on the output from the left file. Figure 11 shows the normalized cross-correlation function, hence the left- and right-ear noise are correlated, for delays  $\gamma = 10$ , and 20 ms, for the output of two matched gamma-tone a d i o files tuned to 500 Hz. The left panel plots the normalized cross-correlation function of

a range of delay from -10 to 30 ms. The right panel plots the same function only over the range of delay that might be considered physiologically realistic. The parameters of this gamma-tone file have been selected to provide the best fit to the spectral profile that characterizes a 500 Hz human a d i o file (Patterson 1976), and has an elevated angular band width of 92 Hz (454-546 Hz). Figure 11 indicates that the observed correlation in our matched left- and right-ear file at this bandwidth, the portion of the normalized cross-correlation function that is in the physiologically plausible range could probably be attributed to the left- and right-ear correlated noise from independent left- and right-ear noise when the interaural delay is 10 ms but not when it is 20 ms. However, if the file width is cut in half (Fig. 12), and the observed correlation in this file, then the observed correlation potential performance for this discrimination at interaural delay as long as 20 ms.

When stimuli are presented over headphones, it is interesting to note that narrowband filtering can account for delay thresholds  $< 10$  ms. Note that the delay threshold for all of the older adults are less than 10 ms in the headphone condition, hence the threshold for younger adults are greater than 10 ms in the same condition. Hence, it is possible that all of the older adults, and for some of the younger adults, a narrowband file might accomplish the task.

Hence, in order for the performance of some of the younger adults to be reduced to be based solely on cross-correlation of the output from matched a d i o files, it seems that the file would have to be narrower than those previously observed. However, it might be possible to bridge longer interaural delays if narrowband filtering of the input at each ear is followed by propagation delays of several milliseconds (as in Durlach's 1972 EC model) before binaural comparison is completed. One could bet that a nonlinearities of one or two orders in a d i o processing could also help bridge the longer delays in some individuals. And the possibility is that higher-order central mechanisms could be involved in maintaining an a d i o trace of the acoustic waveform.

The ability of some listeners to detect interaural correlated and uncorrelated noise has already been found previously in young individuals.

To obtain a PDF file showing how the normalized cross-correlation function and age performance were computed for the output of the file (Fig. 11-13), please contact Bruce Schneider.
